form H2 and OH[−]. Experiments and simulations suggest that this reaction occurs through a mechanism involving colocalization of two e_{hyd}^- 's into the same solvent cavity, forming a hydrated dielectron ((e_{hyd})²−) intermediate, with aqueous hydride (H[−]) as a subintermediate. However, there has been no direct experimental observation of either ($\rm \epsilon_{hyd})_2^{2-}$ or H−. Here, we present TD-DFT-based predictions for the absorption spectrum of open-shell-singlet and triplet *e*_{hyd} pairs, (e_{hyd})²⁻, and H[−]. We find that relative to e_{hyd}, triplet and open-shell singlet electron pairs show spectral shifts to the blue and red, respectively. Additionally, we find that $(e_{hyd})²₂$ absorbs even further to the red, and that H[−] has a charge-transfer-to-solvent-like transition at wavelengths several eV to the blue, providing a direct experimental handle with which to probe these species. We propose a three-pulse transient absorption experiment that should allow detection of $(e_{\text{hyd}})_2^{2-}$ and H⁻.

An excess electron in liquid water forms a stably solvated
species known as the hydrated electron ($e_{\text{hyd}}^{(-)}$).^{1−[5](#page-6-0)} Though
hydrated electrons are the simplest chemical solute they hydrated electrons are the simplest chemical solute, they display a wide array of fascinating properties and have been of considerable experimental^{[4](#page-6-0)-[7](#page-6-0)} and theoretical^{8-[13](#page-6-0)} interest over the last several decades. Experimentally, hydrated electrons are easily made via pulse radiolysis, [4](#page-6-0),[5](#page-6-0),[14](#page-6-0) multiphoton ionization,[15](#page-6-0)−[18](#page-6-0) or the charge-transfer-to-solvent excitation of solvated anions.^{[19](#page-6-0)−[22](#page-6-0)} Theoretically, their treatment results in a challenging but potentially tractable quantum many-body problem.^{23,24} Despite this, there are still many open questions about the e_{hyd}^- namely the nature of the solvation structure around this species $8,9,25,26$ $8,9,25,26$ and how the solvation structure controls its reactivity as a strong reducing agent in solution.^{13,[27](#page-7-0)–[29](#page-7-0)}

Hydrated electrons are known to react with a variety of organic molecules,[30](#page-7-0) and recent *ab initio* simulation work has illuminated some features of this reactivity, $13,28,29$ $13,28,29$ $13,28,29$ $13,28,29$ particularly for the reduction of $CO₂$.^{[13](#page-6-0),[29](#page-7-0)} The reaction of interest for this work, which is common in the radiation chemistry of water, involves two hydrated electrons reacting with H_2O to form hydrogen gas and hydroxide:

$$
e_{\text{hyd}}^- + e_{\text{hyd}}^- + 2H_2O \rightarrow H_2 + 2OH^- \tag{1}
$$

This hydrogen evolution reaction typically takes place in high concentration e_{hyd}^- solutions. These solutions are thought to contain a mixture of single e_{hyd}'s, separate but spin-correlated e_{hyd} pairs with parallel spins (triplet), and separate but spin-

correlated e_{hyd}^- pairs with opposite spins (open-shell singlet). It is also possible that two *e*_{hyd}'s at high concentration can occupy the same cavity in the singlet spin state, a species termed the hydrated dielectron, $(e_{\text{hyd}})_2^{2-}$.

Experiments have observed that atomic hydrogen is not a product of reaction (1) and that the only products are diamagnetic, 31 suggesting that H \cdot is also not a reactive intermediate. Since triplet H_2 is unbound, the hydrated electrons that participate in this reaction, as well as any reactive intermediates, must be spin singlet. 31 Thus, the intermediates in this reaction have been speculated to be the spin-paired hydrated dielectron and/or the aqueous hydride ion.^{[32](#page-7-0)} From experimental measurements of the reaction rate, Schmidt and Bartels estimated that *e*_{hyd}'s within ∼9 Å of each other combine to initiate reaction $(1)^{31}$ $(1)^{31}$ $(1)^{31}$. The mechanism of this reaction is thought to proceed via the following multistep process involving formation of the $(e_{\text{hyd}})_2^{2-}$ intermediate:^{33,34}

$$
e_{\text{hyd}}^- + e_{\text{hyd}}^- \rightarrow + (e_{\text{hyd}})_2^{2-} \tag{2}
$$

$$
(e_{\text{hyd}})_2^{2-} + H_2O \to H^- + OH^-(3)
$$

$$
H^- + H_2O \rightarrow H_2 + OH^-\tag{4}
$$

Despite their potential importance as intermediates in reaction (1), the existence of hydrated dielectrons has not been directly established. Experiments have sought to measure this species using absorption spectroscopy, and early work from Basco et al.^{[35](#page-7-0)} argued that the absorption of the $(e_{\text{hyd}})_2^2$ should occur in the IR at wavelengths >700 nm. However, subsequent works either did not find an IR absorbing species, 36 assigned the dielectron absorption as occurring in the UV , 37 or concluded that there were no absorption signatures consistent with $(e_{\text{hyd}})_2^2$ ^{-[32](#page-7-0)} In alkali metal/ammonia solutions, dielectrons are suspected to play a role in the increased electrical conductivity and decreased spin density that accompany an insulator-to-metal transition observed with increasing alkali metal concentration.[38](#page-7-0) Moreover, in recent work, Hartweg et al.^{[39](#page-7-0)} implicated the formation of dielectrons in ammonia clusters following UV excitation in the presence of alreadyexisting solvated electrons.

Based on all the indirect experimental evidence for solvated dielectrons, there has been a significant theoretical push to
understand their properties,^{[40](#page-7-0)−[45](#page-7-0)} including previous work from our group[.33,46](#page-7-0)[−][48](#page-7-0) *Ab initio* simulations predict that spin singlet hydrated electron pairs in close proximity preferentially occupy the same cavity,^{[33,34](#page-7-0),[49](#page-7-0)} forming $(e_{\text{hyd}})_2^2$, and that spin triplet hydrated electron pairs prefer to occupy separate cavities.^{[34](#page-7-0)} All of the *ab initio* simulations,[34,49](#page-7-0) including ours,[33](#page-7-0) predict that hydrated dielectrons are indeed the primary intermediate of reaction (1) , as specified in reactions (2) and (3) .

Our previous publication studying reactions (2−4) found a range of lifetimes for the $(e_{\text{hyd}})_2^2$ and H⁻ intermediates. We saw that a second electron injected in the presence of an already-equilibrated $e_{\rm hyd}^-$ instantaneously localizes into the same cavity to form $(e_{\text{hyd}})_2^2$, giving a rigorous time zero for starting reaction (2). The $(e_{\text{hyd}})_2^{2-}$ lives for hundreds of femtoseconds, on average, before reaction (3) takes place.^{[33](#page-7-0)} We found that the time scale of this first proton abstraction to form H[−] depends on the existence of a hydrogen bond network to shuttle the OH[−] far from the reaction center through a Grotthus-type 50,51 50,51 50,51 50,51 50,51 proton hopping mechanism.^{[33](#page-7-0)} Once formed, the H[−] intermediate exists for 10 to ∼150 fs, depending on the degree of solvation, before reaction (4) takes place.³³ These relatively short lifetimes are the reason why direct experimental detection of $(e_{\text{hyd}})_2^{2-}$ and H⁻ in reactions that require diffusion of two electrons to start reaction (2) has been unsuccessful thus far.

In this work, we propose that for the possible intermediates for reaction (1) —separated spin-paired singlet or triplet hydrated electron pairs, hydrated dielectrons in a single cavity and solvated H⁻—the best route to investigate them experimentally is through ultrafast transient absorption spectroscopy.

To date, the only studies of hydrated dielectron spectroscopy via simulation was in previous work from our group using mixed quantum/classical simulations;^{46−[48](#page-7-0)} there have been no *ab initio*-based spectroscopic studies of paired hydrated electrons, dielectrons or H[−]. If the absorption spectrum of $(e_{hyd})₂²$ (i.e., two spin singlet electrons localized to the same

solvated cavity) has unique spectral features or dynamic behavior compared to that of a (single) e_{hyd}^- , then it should be possible to experimentally characterize this species if one knew where to look. It is also possible that as two hydrated electrons approach each other en route to reaction (2) , their mutual coulomb repulsion and/or interaction of their solvation structures could affect their spectroscopy in measurable ways. The H[−] intermediate in reaction (3) could also have experimentally identifiable spectral features.

The goal of this paper is to provide *ab initio*-predicted spectral features for all of these species, with the hope of inspiring experimentalists to look for their signatures. We take advantage of trajectories from our previous work 33 to perform a time-dependent density functional theory (TD-DFT) analysis of the spectroscopy of $(e_{\text{hyd}})_2^2$ and H⁻. We also study the spectral behavior of separate but interacting (single) e_{hyd}^- pairs in both the triplet and open-shell singlet spin states. We find that the absorption spectra of both triplet and openshell singlet *e*_{hyd} pairs show noticeable shifts (~0.2 eV) depending on the distance between them. As the distance between the electrons decreases, the absorption spectrum of open-shell singlet *e*_{hyd} pairs red-shifts, while that of spin triplet electron pairs blue-shifts, providing a definitive spectral signature of e_{hyd}^- interaction that could be observed experimentally. We also predict that if a second (opposite spin) hydrated electron is injected in the presence of an already-equilibrated e_{hyd}^- , dielectrons will be formed immediately, with a spectrum that is ∼0.3 eV red-shifted from that of the single e_{hyd}^- . Additionally, we predict that the H⁻ subintermediate has an absorption spectrum that is a few eV blue-shifted from all the other species, providing a unique spectral window for its potential observation. With knowledge of the spectroscopy and lifetimes of the reaction (1) intermediates, 33 we offer a set of specific pump/probe experiments that could be performed to detect these species.

The details of our simulations are largely the same as those used in our previous work^{[9](#page-6-0)} and are described in more detail below in the Methods section. Briefly, we perform AIMD simulations with 64 water molecules and one or two excess electrons in the *N*, *V*, *T* ensemble at 298 K. The $PBE0^{52}$ $PBE0^{52}$ $PBE0^{52}$ exchange-correlation functional was used with 25% exact exchange with Grimme's D3 dispersion correction.^{[53](#page-7-0)} In this work, hydrated (di)electrons are represented using their maximally localized Wannier functions $(MLWFs)$, 54 54 54 and their positions determined as the Wannier orbital centers (WOCs).

Sixteen trajectories were performed in which a second $e_{\text{hyd}}^$ was injected into an already equilibrated e_{hyd}^- system with parallel spins to simulate triplet \vec{e}_{hyd} pairs. We then took 22 equilibrated triplet electron pair congifurations and changed the spin state to antiparallel, thus simulating open-shell singlet *e*_{hyd} pairs. The open-shell singlet systems were run until the *e*_{hyd} pairs recombined into hydrated dielectrons, which occurred in less than 1.5 ps in 13 of our trajectories. Configurations for calculating the spectra of $(e_{\text{hyd}})_2^2$ and H⁻ were taken from trajectories from our previous work.^{[33](#page-7-0)} These $(e_{\text{hyd}})_2^2$ configurations were pulled from trajectories a few hundred fs after injection of the second e_{hyd}^- to provide time for solvent equilibration, and also were sampled prior to the start of reaction (3). Hydride configurations were taken after the completion of reaction (3) and prior to the start of reaction (4).

Absorption spectra were calculated using Tamm-Dancoff approximation (TDA) TD-DFT in CP2K.^{[55](#page-7-0)} These calculations are fully periodic and 10 excited states were used to determine the spectra for *e*_{hyd}/paired *e*_{hyd} systems, while 20 excited states were used for the $({e}_{\text{hyd}})_2^{2-}$ and H^- systems. We note that use of this methodology introduces a significant spectral blue-shift compared to both our previous nonperiodic calculations that used an optimally tuned range-separated hybrid func-tional^{9,11,[56](#page-7-0)} and the experimental spectrum.⁵⁷ This methodology is also known to sometimes include spurious charge transfer transitions, $9,58$ $9,58$ $9,58$ and these are removed from our spectra using the so-called "Ghost Hunter" index.⁵⁹ Further details can be found in the [Methods](#page-5-0) section and [SI.](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf) However, use of the periodic TD-DFT methodology does allow us to make rigorous relative spectral comparisons between each of the electron-based species explored in this work. Further details on calculation of the absorption spectra are provided in the Methods section.

To understand the spectral features of the intermediates associated with reaction (1) , we start by examining what happens when hydrated electrons are present in close proximity (i.e., the left side of reaction (2)). Previous experiments have initiated reaction (2) through the generation of high-concentration e_{hyd} solutions via either pulse radiol-ysis^{31,[32](#page-7-0)} or flash photolysis.^{[35,37](#page-7-0)} It is thought that singlet $e_{\text{hyd}}^$ pairs can combine via diffusion to form $(e_{\text{hyd}})_2^2$, while triplet e_{hyd} pairs cannot form dielectrons.^{[31](#page-7-0)} The questions we now address pertaining to reaction (2) are: do spin-correlated *e*hyd − pairs have spectral features that are distinct from those of the equilibrium hydrated electrons? Is there any difference between the absorption spectra of singlet and triplet $e_{\rm hyd}^-$ pairs?

In Figures 1b and d, respectively, we report the electron− electron distance $(r_{1,2}, \text{ calculated as the distance between})$ WOCs) dependent absorption spectra of triplet (blue curves) and open-shell singlet (green curves) $e_{\rm hyd}^-$ pairs. The black dashed line in each panel marks the peak of the equilibrium absorption spectrum of the (single) e_{hyd}^- calculated using the same methodology. At relatively far distances $(r_{1,2} \geq 5.7 \text{ Å})$, the spectra of triplet and open-shell singlet e_{hyd} pairs matches that of single hydrated electrons; the electron pairs also have similar solvation structures as single hydrated electrons [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf) [S5](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf) in the [SI](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf)). As $r_{1,2}$ decreases, however, we observe significant (∼0.2 eV) shifts of the spectra of triplet and open-shell singlet electron pairs: the spectrum blue-shifts as triplet-paired electrons approach each other, but red-shifts when the electrons' spin are open-shell singlet.

Spectroscopically, hydrated electrons behave roughly as particles in a spherical box, with three quasi-degenerate $s \rightarrow p$ electronic transitions.^{[60](#page-7-0)} Indeed, visualization using natural transition orbitals^{[61](#page-7-0)} [\(Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf) S6 in the [SI\)](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf) show that our TD-DFT-calculated spectral transitions do resemble $s \rightarrow p$ transitions. In the spherical box model, the excitation energies depend on the size of the box, which for a e_{hyd}^- is roughly its radius of gyration (*Rg*). Figures 1a and c show scatter plots of the average radius of gyration, ⟨*Rg*⟩, calculated from the MLWFs of both electrons, versus $r_{1,2}$ for triplet and open-shell singlet electron pairs, respectively. The solid black lines are least-squares fits to the data points to emphasize the trends. Clearly, the $\langle R_g \rangle$ of triplet e_{hyd} pairs decreases and that of openshell singlet *e*_{hyd} pairs increases as the electrons approach each other. This trend correlates well with the observed spectral shifts, with smaller box sizes for triplet pairs increasing the

Figure 1. Comparison of the average radius of gyration, $\langle R_{\varphi} \rangle$, panels (a) and (c), and the TD-DFT-calculated absorption spectra, panels (b) and (d), as a function of the electron−electron distance, (*r*1,2), for triplet and open-shell singlet hydrated electron pairs, respectively. The black lines in panels (a) and (c) are least-squares fits to the data points to emphasize the trends. The $\langle R_{\nu} \rangle$ of triplet electron pairs decreases as the electrons approach each other while that of openshell singlet electron pairs increases. This leads to a blue-shift of the spectrum of triplet pairs and a red-shift of that of open-shell singlet pairs relative to the spectrum of (single) hydrated electrons, whose spectral maximum is indicated by the black dashed lines in panels (b) and (d). Panel (e) plots the electron−electron MLWF overlap for both types of electron pairs as a function of $r_{1,2}$. When in close proximity, open-shell singlet electron pairs (green data points) are able to overlap while triplet pairs (blue data points) are not, explaining the observed trends in ⟨*Rg*⟩.

excitation energies while larger box sizes for singlet pairs decrease excitation energies as the electrons get closer to each other.

The fact that singlet and triplet e_{hyd}^- pairs have opposite spectral trends with distance is likely due to Pauli repulsion. As the e_{hyd} cavities become closer together, the parallel spins of triplet e_{hyd}^- pairs prevent the two electrons from overlapping in space. This Pauli repulsion causes each $e_{\rm hyd}^-$ to decrease its $R_{\rm g}^-$ to accommodate the proximity of the other electron. For openshell singlet pairs, in contrast, electrons with opposite spin can overlap in close proximity; this means that each electron can slightly occupy the other's cavity, increasing their $\langle R_{\varrho} \rangle$. Figure 1e plots the electron−electron overlap for triplet (blue data points) and open-shell singlet (green data points) e_{hyd}^- pairs, calculated as the dot product of their MLWF densities. The data show that the open-shell singlet electron−electron overlap increases with decreasing *r*1,2 while the triplet electron− electron overlap remains close to zero as the electrons approach each other, consistent with the distance-dependent trends in $\langle R_g \rangle$. Additionally, the absence of configurations with closer $r_{1,2}$ highlights the significant energetic barrier for triplet e_{hyd}^- pairs to spatially overlap.

The data in Figure 1 predict that there is a distinct spectral feature associated with the recombination of singlet e_{hyd}^- pairs

that may be detectable via transient absorption spectroscopy. One possible experiment would be to generate a high concentration of e_{nyd} 's via some short-pulse method, such as pulse radiolysis,^{[31](#page-7-0),[32](#page-7-0)} charge-transfer-to-solvent excitation of a dissolved anion like I $^-$ or ${\rm [Fe(CN)_6]}^{4-19-22}$ ${\rm [Fe(CN)_6]}^{4-19-22}$ ${\rm [Fe(CN)_6]}^{4-19-22}$ ${\rm [Fe(CN)_6]}^{4-19-22}$ ${\rm [Fe(CN)_6]}^{4-19-22}$ or direct multiphoton ionization of water. $15-18$ $15-18$ $15-18$ It is well-known that following their initial injection, nonequilibrated hydrated electrons absorb to the red of the equilibrium e_{hyd}^- spectrum, but equilibration is known to be complete in ≤ 1 ps after injection.[20](#page-6-0)[,62](#page-7-0)[−][64](#page-7-0) Once equilibrated, if the concentration is high enough, a subset of the electrons will be paired as openshell singlets, producing a red shoulder in the transient absorption spectrum that should decay on the time scale of reaction (2), leaving the equilibrium (single) $e_{\rm hyd}^-$ spectrum behind. It might also be possible to pick up the spectral signatures of proximal triplet $e_{\rm hyd}^-$ pairs (for which there should

be three times as many as singlet pairs given the spin statistics) as a blue shoulder on the equilibrium spectrum, although this may be harder to detect given that the equilibrium spectrum has a strong absorption tail to the blue.⁵

It is worth noting, however, that our simulations predict a significant absorption spectral shift only at quite small electron−electron distances. If the paired hydrated electrons are separated by ≥ 6 Å, their spectra are indistinguishable from those of equilibrated single hydrated electrons. If the reaction distance of ∼9 Å estimated for reaction (2) is correct,^{[31](#page-7-0)} then there would be very little transient population of singlet *e*_{hyd} pairs relative to single hydrated electrons, thus decreasing the chance of detecting this species via transient absorption spectroscopy.

Given the challenges in measuring the spectral shifts of hydrated electron pairs at high concentrations, we next
propose a different experiment^{46−[48](#page-7-0)} that should provide better access to detect the presence of the $(\epsilon_{\rm hyd})_2^{2-}$ and possibly also the H[−] reactive intermediates. First, a short laser or radiolysis pulse could be used to generate hydrated electrons. After a time delay to ensure that this population reaches equilibrium, a second pulse could then used to generate additional electrons; based on our previous simulations, 33 some of these will colocalize into the same cavity as a pre-equilibrated hydrated electron, directly creating $(e_{\text{hyd}})_2^{2-}$. The second pulse thus provides a rigorous time zero for the generation of a $\left(e_{\rm hyd}\right)^2_2$ population, which is expected to live for ∼1 ps.^{[33](#page-7-0)} The questions we explore next is what are the spectral features of the dielectron, and is there is an experiment that could also detect the H[−] subintermediate?

Figure 2 plots radial distribution functions (RDFs) between the centers of the electron (black dashed curves), dielectron (orange curves) and the H (panel a) or O (panel b) atoms of the surrounding water molecules; panel c shows running coordination numbers calculated by integrating the center-tooxygen RDFs. The data show that the hydrated dielectron has a slightly larger cavity than the (single) e_{hyd}^- as seen from the fact that its first shell peaks sit at a farther distance. The running coordination number shows that the larger and more highly charged $(e_{\text{hyd}})_2^{2-}$ has an additional coordinating water molecule (~6) compared to the single $e_{\rm hyd}^-$ (~5).^{[10](#page-6-0)} We also find an R_g of 2.91 Å for $(e_{\text{hyd}})_2^2$ compared to 2.51 Å for the single e_{hyd}^- as calculated using their MWLF densities. All of these measures indicate that the hydrated dielectron sits in a

Figure 2. Radial distribution functions (RDFs) of the hydrated electron, hydrated dielectron, and hydride from our DFT-based simulations. Panel a shows center to water H RDFs, panel b shows center to water O RDFs, and panel c shows the running water coordination number of each species. The black dashed, orange, and plum curves correspond to the hydrated electron, hydrated dielectron, and hydride, respectively. The positions of the first-shell H and O atoms are slightly farther for dielectrons than for (single) hydrated electrons, indicating a larger cavity. The running coordination number shows that the larger dielectron has ∼6 first-shell waters, which is more than the ∼5 of the single hydrated electron. Since hydride is generated when the dielectron abstracts a proton from a coordinating water and does not have time to equilibrate, the H[−] solvation structure is similar to that of the dielectron water structure, though perturbed.

larger cavity than the hydrated electron, which along with the electron−electron repulsion should give a distinct spectral signature that could be detected by transient absorption.

Figure 2 also shows the solvation structure of the H[−] subintermediate (plum curves). Our previous simulations indicate that H[−] lives for ≤100 fs due to the rapid rate of reaction (4) ,^{[33](#page-7-0)} so the solvent structure of this species never fully comes to equilibrium before it reacts. As a result, H[−] largely adopts the solvation structure left behind by the $(e_{\text{hyd}})_2^2$ that created it from reaction (3) , so the two species have generally similar RDFs. We note that H⁻ is significantly smaller than the dielectron due to coulomb attraction from the central proton, which allows some of the first-shell waters to move closer to the H⁻ center prior to reaction (4) , as seen by the tails toward smaller distances in the RDFs.

[Figure](#page-4-0) 3 plots the TD-DFT calculated optical absorption spectra of the hydrated electron (black dashed curve), hydrated dielectron (orange curve), and hydride (plum curve). The $(e_{\text{hyd}})_2^2$ spectrum exhibits a significant red-shift

Figure 3. TD-DFT calculated and normalized absorption spectra of the hydrated electron (black dashed curve) and the hydrated dielectron (orange curve) and hydride (plum curve) reactive intermediates. Relative to the spectrum of the single e_{hyd}^- , the absorption spectrum of the dielectron intermediate shows a significant red-shift, providing a signature that could be detected experimentally. The hydride subintermediate exhibits a large spectral blue shift relative to the other species, offering another potential spectroscopic signature that could be used to test the mechanism of reaction (1).

of ∼0.3 eV compared to that of the single e_{hyd}^- . This red-shift results from both the fact that the dielectron has a larger cavity and thus R_{σ} and the fact that the coulomb and exchange repulsion between the two electrons should raise the groundstate energy more than the excited-state energies relative to the (single) e_{hyd}^- . We note that the spectral shift is larger than that of the open-shell singlet *e*_{hyd} pair in close proximity due both to the larger R_g and the stronger coulomb/exchange repulsion of $(e_{\text{hyd}})_2^2$ from greater electron overlap.

Our prediction is that if one were to create dielectrons with two sequential pump pulses to induce colocalization, a third probe pulse should be able to detect them by probing at wavelengths on the red side of the single e_{hyd}^- absorption spectrum. This prediction falls along the same lines as Basco et $aL₁³⁵$ $aL₁³⁵$ $aL₁³⁵$ who also concluded that the signature absorption of the dielectron occurs in the IR at wavelengths >700 nm. The one caveat for this experiment is that the predicted lifetime of $(e_{hyd})₂²$ is comparable to the solvation relaxation time of the (single) electrons generated by the second pump pulse, so precise characterization of the solvation dynamics following the first pump pulse will be needed to determine if the second pump pulse produces an additional red-shifted spectral feature associated with dielectrons.

Our simulations also predict that even though the H[−] subintermediate has a much shorter lifetime than $(e_{\text{hyd}})_2^2$, it might be easier to detect spectroscopically: the plum curve in Figure 3 suggests that H[−] absorbs several eV to the blue of hydrated electrons and dielectrons. In the gas phase, H[−] does not have any bound electronic excited states,⁶⁵ but the presence of surrounding solvent can create bound excitations, referred to as charge-transfer-to-solvent (CTTS) states. The position of the H[−] absorption band fits well to assignment as a CTTS transition. Previous calculations predicted that the CTTS spectrum of aqueous Na[−] would be at ~3 eV,^{[66](#page-8-0)} and one would expect the H[−] CTTS excitation to be higher in energy than that of Na[−] based on the higher electron affinity of H relative of Na. In the [SI](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf), we provide snapshots of the H[−] NTOs associated with the strongly allowed TD-DFT transitions,

which do somewhat resemble what might be expected for a CTTS transition.

In conclusion, we report predicted spectroscopic signatures of the reactive intermediates that take part in reaction (1). Direct measurements of open-shell singlet and triplet e_{hyd}^- pairs might be feasible in experiments generating high concentrations of e_{hyd}^- through short-pulse methods: open-shell singlet *e*h_{yd} pairs are predicted to exhibit a detectable red shoulder on the equilibrium e_{hyd}^- absorption spectrum, while triplet electron pairs in close proximity should exhibit a blue shoulder, leading to a potentially observable broadening of the spectrum relative to the spectrum of single hydrated electrons. For hydrated dielectrons, despite a large amount of theoretical interest, there has yet to be any direct observation by experiment. To remedy this, we have proposed the following three-pulse transient absorption experiment to detect this important intermediate.

The first pulse in this experiment is used to generate single hydrated electrons in solution. Techniques such as multi-photon ionization,^{[67,68](#page-8-0)} CTTS excitation of anions,^{[19](#page-6-0)−[22](#page-6-0)} or pulse radiolysis^{[31](#page-7-0)} can generate high concentrations of injected hydrated electrons, in some cases up to decimolar concentrations.[67](#page-8-0) These conduction band electrons are then allowed to equilibrate into hydrated electrons. This first set of hydrated electrons would have a half-life of up to microseconds, $\frac{69}{2}$ providing ample time and trap density for the introduction of the secondary pulses for electron capture and subsequent probing.

Once the first population of hydrated electrons is equilibrated, a second set of hydrated electrons is then injected into the solution via one of the methods listed above. Our previous experiments have shown that injected electrons in aqueous NaCl solutions preferentially localize near $Na⁺$ traps rather than localizing independently into cavities irrespective of traps.[70](#page-8-0) Other experimental work that injected electrons at decimolar concentrations into liquid water observed saturation of the available traps, forcing these electrons to remain delocalized in the conduction band until additional traps became available.^{[67](#page-8-0)} These results suggest that injected electrons are always trap-seeking, and thus should prefer to localize in the cavities of pre-existing hydrated electrons rather than elsewhere in the liquid. Indeed, our previous theoretical work^{[33,46](#page-7-0)−[48](#page-7-0)} has shown that injected electrons are captured with 100% efficiency if a previously equilibrated hydrated electron is available. Moreover, theoretical work by Bu and coworkers has shown that hydrated dielectrons are energetically more stable than two separate single hydrated electrons.³⁴ Together, this body of experimental and theoretical work suggests that equilibrated hydrated electrons, which can be produced in decimolar concentrations,^{[67](#page-8-0)} can serve as traps for injected conduction band electrons (if they are spin antiparallel).

One caveat with the source of the secondary injected conduction band electrons is that their introduction should not directly perturb the population of pre-existing electrons. For example, if one were to create the secondary electrons via multiphoton ionization at 266 nm, [67,68](#page-8-0) some of the pre-existing electrons might also be excited at this wavelength, leading to signals that could confound the observation of dielectrons. However, hydrated electrons have a very low absorption crosssection at 266 nm,^{[3](#page-6-0)} and if one generated the secondary electrons via CTTS excitation of a strongly absorbing species like $K_4Fe(CN)_{67}^{70,71}$ $K_4Fe(CN)_{67}^{70,71}$ $K_4Fe(CN)_{67}^{70,71}$ nearly all of the light would be absorbed

Once the secondary electrons are injected, 25% of them should have singlet-paired spins with the pre-existing hydrated electrons; as argued above, the fact that hydrated electrons are trap-seeking suggests that a significant fraction of these should be captured by the pre-existing electrons to form dielectrons. The dielectrons have a unique spectral feature, absorbing well to the red of single hydrated electrons. Of course, the "hot" injected electrons that do not recombine into dielectrons will also absorb to the red of the single hydrated electron, but the spectral kinetics of hot electron relaxation have been well-studied since the 1980s.^{[20](#page-6-0),[62](#page-7-0)-[64](#page-7-0)} In our proposed 3-pulse experiment, the spectral relaxation of "hot" single hydrated electrons can be well characterized after the first excitation pulse, so that one could look for spectral differences associated with the second excitation pulse that would be indicative of dielectron formation. Given that the lifetime of hydrated dielectrons in our simulations is predicted to be longer than the relaxation time of single injected electrons, 33 it should be possible to see the singlet hydrated dielectrons after any tripletpaired hydrated electrons and noncaptured singlet hydrated electrons have finished their relaxation process.

Spectral detection of hydrated dielectrons will be aided by the fact that their oscillator strength is twice that of single hydrated electrons, so that it may be possible to isolate their spectral signatures even if only a few percent of the secondary hydrated electrons are converted to dielectrons. If needed, one could also run the experiment at higher temperatures, where the rate of dielectron conversion to hydrogen slows down, $31,72$ $31,72$ possibly extending the lifetime of this important reactive intermediate.

We also predict that the same 3-pulse experiment might be able to detect the hydride ion subintermediate by probing deep in the UV, providing possible proof of the mechanism suggested by reactions (3) and (4) . We acknowledge that the hydride lifetime as characterized by our previous work 33 , is short (order tens to ∼100 fs), however, the distinctness of its spectral signature relative to the other intermediates may make its detection feasible, albeit difficult.

■ **METHODS**

To simulate the hydrated dielectron via sequential injection of an excess electron into an already equilibrated single electron system, 33 we used starting configurations from our previously published single hydrated electron simulations.^{[9](#page-6-0)} These simulations were done with the $CP2K^{73}$ software package in the *N*, *V*, *T* ensemble at a temperature of 298 K. The simulation cell contained 64 water molecules with a cell length of 12.427 Å. A time step of 0.5 fs was used, and a Nose-Hoover⁷⁴ chain thermostat was coupled to the system to maintain the target temperature. The volume of the system was chosen to reproduce the experimental density of water at 298 K and 1 atm. The PBE0 exchange-correlation functional with default 25% exact exchange, Grimme's D3 dispersion $correction₁⁵³$ $correction₁⁵³$ $correction₁⁵³$ and Goedecker-Teter-Hutter(GTH) pseudopo-tentials^{[75](#page-8-0)} along with the TZVP-GTH basis set were used in these simulations. Hartree−Fock (HF) exchange calculations were expedited by way of an auxiliary density matrix method.⁷⁶ We acknowledge that other groups have simulated the hydrated electron with the PBE0 functional using 40% exact exchange, $10,12$ $10,12$ including work studying the DEHE reaction.³⁴ Our previous work has shown that the resulting solvation

structure for 25% or 40% exact exchange PBE0 are nearly identical.^{[9](#page-6-0)} Moreover, the agreement of our current work with that of Bu and co-workers³⁴ indicates that, for the case of dielectron reactivity, varying the amount of exact exchange over this range does not make a significant difference.

Absorption spectra calculations were done using Tamm-Dancoff time-dependent density functional theory⁵⁵ (TD-DFT) in CP2K.⁷³ The calculations were fully periodic and for each configuration, 10 excited states were calculated for the *e*_{hyd} and paired e_{hyd}^- systems, while 20 excited states were used for the $(e_{\text{hyd}})_2^2$ and H⁻ species. Approximately 50–100 configurations were used for each system.

Previously, we calculated the absorption spectrum of the (single) hydrated electron using a nonperiodic TD-DFT methodology suggested by Uhlig et al., $\frac{1}{7}$ which involves periodic replication of point charges around the quantum box, removal of periodic boundary conditions, and the use of an optimally tuned range-separated hybrid functional. Unfortunately, for the simulations presented here, the process of replication is complicated by the inclusion of two electrons that in many configurations exist relatively far apart. This led to difficulties with performing this replication because electrons near the edge of the simulation box did not remain localized in their cavities. Therefore, we decided to do fully periodic TD-DFT calculations to obtain the absorption spectra in this work. We note that this makes comparing the spectra presented here to those presented in previous work more difficult, but this choice allows for a detailed comparison of the spectra of the different intermediates that are calculated at the same level of theory.

As mentioned above, calculating the spectra using periodic TD-DFT calculations also leads to issues with spurious charge transfer states, $59,78,79$ $59,78,79$ so to remedy this we employed the so-called ghost hunter index^{[59](#page-7-0)} to identify and remove such spurious states. We found that the only spurious states with non-negligible oscillator strengths appeared on the red-side of the calculated spectrum and that there were no nonspurious states in this region, so we also implemented an energy cutoff whereby transitions with energies below the cutoff were removed from our spectral calculations. Details of how we developed the cutoff are shown in the [SI](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf).

In our previous work, 9 where the single electron absorption spectra was calculated using the nonperiodic TD-DFT methodology of Uhlig et al., $\frac{1}{\sqrt{7}}$ the peak of the absorption spectrum occurred at an energy of 2.52 eV, which is already significantly blue-shifted from the experimental absorption peak at 1.73 eV.^{[80](#page-8-0)} For the periodic TDA TD-DFT calculations of the single hydrated electron in this work, we find that the calculated peak is further blue-shifted by ∼0.4 eV, lying at 2.92 eV. This additional blue shift likely results from a combination of periodic boundary effects and the use of the PBE0 functional instead of the optimally tuned range-separated hybrid *ω*-PBE functional.

For the structural analyses used in this work, including the RDFs and calculation of R_g and $r_{1,2}$, maximally localized Wannier functions (MLWFs) were used to represent the hydrated electron(s). We used the Wannier orbital centers to determine of the positions and radii of gyration of the (di) electron (s) . We note that this measure provides a slightly different center position than the spin density or SOMO that we explored in our previous work.^{[9](#page-6-0)} We made this choice because the spin density cannot be used for the hydrated

dielectron or open-shell singlet electron pairs because both electrons occupy the same spatial orbital with opposite spins. A similar issue affects triplet electron pairs, whose Kohn−Sham orbitals are near-degenerate, so that each hydrated electron can partially occupy both cavities, leading to an artificially high *Rg* and skewing the calculated center to lie between the two cavities. Our choice to use MLWFs thus allowed us to analyze all the two-electron systems on the same theoretical footing. A comparison of *Rg* calculated using the spin density, SOMO and MLWF representations of the e_{hyd}^- can be seen in [Figure](https://pubs.acs.org/doi/suppl/10.1021/acs.jpclett.4c02404/suppl_file/jz4c02404_si_001.pdf) S4 in the SI.
